## Abstract

**Background:** *Helicobacter pylori* (*H. pylori*) infection affects about 50% of the world population and its association with environmental factors and host properties is involved in gastric carcinogenesis. The study aimed to estimate the prevalence of *H. pylori* in samples of gastric mucosa biopsies, correlate the presence of the bacteria in the sample with the variables age, sex and origin, to identify the types of lesions found in patients with *H. pylori*, and to evaluate the association of the lesions with the region of the gastric mucosa.

**Methods:** A cross-sectional, retrospective study was carried out in Aracaju, Sergipe, Brazil, from January 2013 to December 2015. A total of 45,206 gastric mucosal biopsies were obtained from patients submitted to upper gastrointestinal endoscopy. Of the reports evaluated, 12,909 met the inclusion criteria since they presented the patient's demographic data as well as the histopathological characteristics of gastric mucosal regions and positivity for *H. pylori*. Data were analyzed by IBM SPSS Statistic 20 and subjected to descriptive analyses (categorical variables) and inferential (Pearson's Chi-square and linear association tests) and multiple correspondence analyses. Significance level adopted 5%.

**Results:** Of the total of 12,909 (28.6%) reports evaluated, 67% (8,647) came from urban areas and 64.5% (8,320) were female. The mean age (standard deviation (SD)) was 43 years, ranging from 8 to 100 years, prevailing between 21 and 60 years. Among the types of gastric mucosa analyzed, 95.5% (12,322) were of the antral mucosa. The absence of glandular atrophy, the mild infection intensity for *H. pylori*, the absence of metaplasia, the presence of foveolar hyperplasia and lymphoid follicles were statistically significant ( $P < 0.001$ ) in this region. In the fundic region, the evidence of fibrinoleucocytic

crust and lymphoid follicles was significant ( $P < 0.001$ ). There was no evidence of associated ulcerated lesions or significant relationship with intestinal metaplasia in the antral mucosa, whereas the fundic mucosa had a strong association with lymphoid follicles. The prevalence of active *H. pylori* infection in this study was 30.93%.

**Conclusion:** Detection rate of *H. pylori* and its association with acute and chronic inflammation should be taken into account. The antral region has shown higher incidence and the presence of *H. pylori* was strongly associated with foveolar hyperplasia and lymphoid follicles.

**Keywords:** *Helicobacter pylori*; Gastric mucosa; Prevalence of *Helicobacter pylori*; Atrophy; Intestinal metaplasia

## Introduction

For over 100 years, micro-organisms have been observed in the gastric tissue, and its association with gastritis has been known since the 1970s. In 1982, Marshall and Warren identified and cultivated *Campylobacter pyloridis*, later called *Helicobacter pylori* (*H. pylori*) [1].

*H. pylori* is a spiral-shaped gram-negative and microaerophilic [2]. Its ability to proliferate and survive in the gastric environment is due to factors such as the production of urease by the microorganism, its motility and ability to adhere to the gastric epithelium. The way through which the infection occurs remains unknown. However, person to person transmission appears to be the most likely one, either through fecal-oral or oral-oral exposure [3].

Conservative approaches to this issue suggest that 50% of the population is affected by *H. pylori* and it is considered the commonest bacterial infection in humans [4]. Genetic sequencing analysis suggests that humans have been infected with *H. pylori* since their first migration from Africa some 58,000 years ago [5]. Once acquired, the infection persists and may or may not produce gastrooduodenal disease [3]. The prevalence of the infection varies according to age, socioeconomic status and ethnicity. Socioeconomic status is also an important determinant and inversely correlated to *H. pylori* infection [6]. Furthermore, within any age range, the infection appears to be more common amongst blacks and Hispanics compared to whites [7].

In developing countries, where most children are infected

doi: <https://doi.org/10.14740/gr785w>

before the age of 10, the prevalence in adults reaches more than 80% before aged 50. In developed countries, like the United States, the evidence of the infection among children is very unlikely to happen, but it becomes more common during adulthood [7]. The increase in the prevalence of infection with age was initially thought to represent a continuous rate of acquisition of the bacterium throughout the life. However, new epidemiological evidence indicates that most infections are acquired during childhood, even in developed countries [7].

Recent studies [6] suggest that, in developing countries, such as Iran, hygiene practices in childhood and family education determine the prevalence of the infection. In Japan, from 1950 on, there was a rapid decline of the infection rate attributed to the economic progress of the post-war period and improved sanitation [8]. The quality of life and socioeconomic conditions should be considered risk factors to acquire *H. pylori* infection [9].

The chronic inflammation induced by *H. pylori* interferes with the normal physiology of the gastric acid secretion in different degrees, thus leading to chronic gastritis, which, in most individuals, remains asymptomatic and does not progress. However, in some cases, altered gastric secretion, associated with tissue injury, induces the development of peptic ulcer, whereas in other cases, gastritis progresses to atrophy, intestinal metaplasia, and eventually to gastric carcinoma or rarely to gastric lymphoma, due to the persistent immune stimulation of the lymphoid tissue [10].

The gastritis can be classified based on the severity of the mucosal lesion as erosive or non-erosive, according to the site of gastric involvement (cardia, body and antrum) and histologically, as acute or chronic based on the type of inflammatory cell. However, no classification scheme fits perfectly into pathophysiology, and the evolution of gastric atrophy involves different clinical and pathophysiological consequences. Gastric gland atrophy may be present in several lesions, especially gastritis, which can progress to the multifocal gastritis associated with the bacterium *H. pylori* and atrophic gastritis of the body, not dependent on the presence of the bacterium [11].

In view of the above, it is necessary to identify the prevalence with *H. pylori* infection, independently of associated lesions, in order to discuss these aspects with the purpose of contributing to their reduction. The study aimed to: 1) determine the prevalence of *H. pylori* in samples of gastric mucosa biopsies (antrum, body, cardia and fundus), obtained through upper digestive endoscopy and original reports of surgical pathology in a pathology laboratory Aracaju, Sergipe, Brazil; 2) correlate the presence of *H. pylori* in gastric biopsy material with the variables such as age, region (urban versus rural) and sex; 3) identify the types of lesions found in gastric mucosa with *H. pylori* positive; and 4) evaluate the association of the lesions found with the biopsied gastric mucosal region.

## Methodology

Between January 2013 and December 2015, a cross-sectional, retrospective study was performed at the Laboratory of Pathological Anatomy Dra. Monica Araujo (LAPMA), in Aracaju,

Sergipe, based on the analysis of gastric mucosa reports obtained through biopsies of gastric mucosa from body, antrum, cardia and fundus, with *H. pylori* infection, regardless of whether through endoscopy and/or specimens of surgical resection. Reports from specimens of surgical resection were excluded because they presented incomplete information. During the research period, 45,206 biopsies were performed for the study of *H. pylori* from endoscopic gastric mucosa biopsy. Of this total, 13,986 reports were evaluated because they presented a positive result for the bacterium, and 1,077 were excluded because they did not meet the inclusion criteria, i.e., all reports should present the patients' demographic data, histopathological characteristics of the biopsied regions of the gastric mucosa and positivity for *H. pylori*. The final sample consisted of 12,909 biopsy reports.

A questionnaire was used as a data collection tool to identify the anatomopathological profile of the mucosa, which consisted of a tab with multiple-choice and short-text questions, elaborated by the researchers, having as dependent variable, the existence of *H. pylori* and independent variables: the patients' demographic characteristics (name, age, urban vs. rural region and sex); the histopathological characteristics of the antrum, fundus, cardia and body regions of the gastric mucosa such as the presence of chronic inflammation and inflammatory activity; glandular atrophy; intestinal metaplasia; evidence of ulcerated lesion; presence of fibrinoleukocytic crust, foveolar hyperplasia, lymphoid follicles, granulomas and other alterations, and the intensity of *H. pylori* colonization. The degree of intestinal metaplasia, classification of glandular atrophy and intensity of *H. pylori* colonization were performed according to the Sydney System [11]. The histological diagnosis of gastritis with and without *H. pylori* infection based on the Sydney System allowed to classify it histologically and to identify its topographic distribution from gastric biopsy.

As for the methodology used for the staining of the gastric biopsy fragments, for the histological examination, the fragments were deposited in bottles identified topographically, containing 10% formalin solution and led to a routine histological process, then subjected to 5  $\mu$ m cuts and stained with hematoxylin-eosin and Giemsa.

To analyze the data, descriptive and inferential analyses were performed. In the descriptive ones, the categorical variables were presented by means of simple frequency and percentage, as for the continuous ones, through mean and standard deviation (SD). In the inferential analysis, Pearson's Chi-square association and line tests were used. In order to evaluate the histopathological profile of the biopsied regions of the gastric mucosa, the perceptual map was constructed from the multiple correspondence analyses. The significance level adopted was 5% and the software used for the analysis was IBM SPSS Statistics 20.0. The study was approved by the Committee of Ethics and Research of the Universidade Tiradentes-CEP/UNIT (CAAE: 49195515.4.0000.5371).

## Results

Endoscopic gastric biopsies totaled a sample of 45,206 biop-

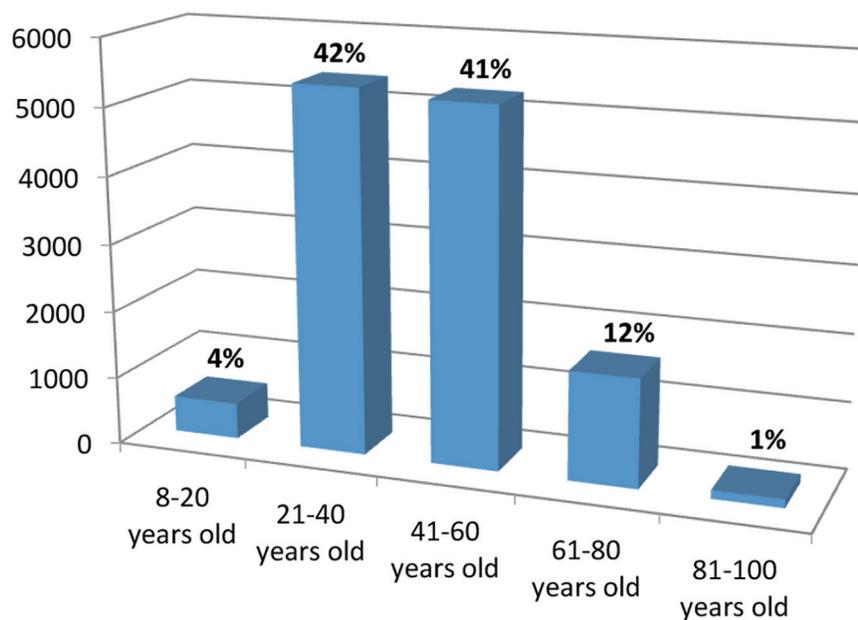

Figure 1. Age group of patients with positive *H. pylori* infection.

sies. Of the total sample, 13,986 were *H. pylori* positive, which translates into a prevalence of 30.93% (45,206). For data analysis, 12,909 reports met the inclusion criteria. Regarding sociodemographic variables, 8,320 (64.5%) of the samples were female and 4,589 (35.5%) were male. Of the samples, 8,647 (72.3%) were from urban areas. The mean age (SD) was 43 years (14.5%), and the age range of the sample varied from 8 to 100 years, being more prevalent between 21 and 60 years (Fig. 1).

As for the prevalence of gastric mucosa types and levels of infection, the antral mucosa was stated to appear the most representative fragment, corresponding to 95.5% (12,322) of the samples. It was also observed that 45.4% (5,857) of them had mild infection and 43.3% (5,587) presented moderate infection levels (Table 1).

The lesions were characterized as: glandular atrophy, intestinal metaplasia (specialized glands of the gastric body are replaced by intestinal type cells), ulcerations (gastric and duodenal ulcers), fibrinoleucocytic crust, foveolar hyperplasia, lymphoid follicles, granulomas, in addition to chronic inflammation and evidence of inflammatory activity. The absence of glandular atrophy was observed in 93.2% (12,033) of the biopsies. The mild type level of angular atrophy appeared in 6.1% (793) of the samples. In this study, 89.5% (11,548) of the cases had no intestinal metaplasia. In the 10.5% of cases with intestinal metaplasia, focal type was the most frequent when compared to diffuse and multifocal metaplasia. Some of the histologic features examined in this study were shown in Figures 2 and 3.

The presence of lymphoid follicles was more often observed compared to other alterations found (gastric and duodenal ulceration, fibrinoleucocytic crust, presence of foveolar hyperplasia and granulomas) (Table 2).

Regarding the relationship between the inflammatory process and the biopsied regions of the gastric mucosa, in all the regions evaluated, there was predominance of moderate degree, both in chronic inflammation and in the presence of inflammatory activity (Table 3).

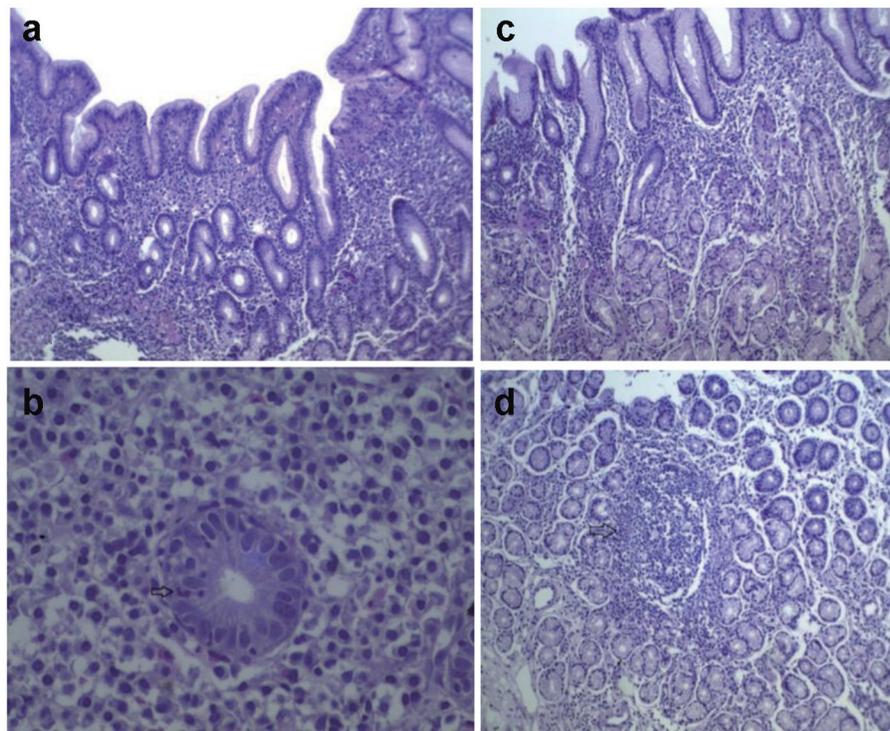

Comparing the histopathological findings between the antrum and other regions of the stomach, the antral region has a higher rate ( $P < 0.001$ ) of glandular atrophy, *H. pylori* infection level, presence of foveolar hyperplasia and lymphoid follicles (Table 4).

In the fundic region, an evidence of fibrinoleucocytic crust and lymphoid follicles were significant ( $P < 0.001$ ) when compared to other regions of the gastric mucosa (Table 5).

Through the multiple correspondence analyses, the anatomo-

mopathological profile of the antral and fundic mucosa was observed due to the proximity between the objects. In the antral mucosa, in addition to the presence of *H. pylori* degrees of mild to moderate, there was significant relationship with the absence of glandular atrophy, absence of associated ulcerated lesions and absence of intestinal metaplasia (Fig. 4).

Fundic mucosa displayed a strong association with the lymphoid follicles, partially linked to the mild and moderate levels of *H. pylori* infection, partially associated with the absence of glandular atrophy and absence of foveolar hyperplasia (Fig. 5).

infection in humans [12, 13]. The prevalence of infection varies from age to age, ethnicity and especially socioeconomic status which is an important determinant and inversely correlated with the infection [4, 6].

The present study displayed a *H. pylori* infection preva-

lence of 30.93%. Previous studies [14-16] ranged from 26.91% to 76% in prevalence putting the present study close to the lower range point. Although the literature points out that *H. pylori* serum-prevalence is equally distributed in men and women, in this study, females had a higher prevalence, and the mean age

**Figure 4.** Pathological profile of the antral mucosa.

biopsy samples, evidenced the hypothesis of an important link between lymphoid follicles and infection [25]. The presence of foveolar hyperplasia in the gastric mucosa occurs in patients with normal histological presentation of gastric mucosa. It may, however, be a consequence of chronic inflammation and its association with *H. pylori* [26]. This finding had significant value ( $P < 0.001$ ) in both the antrum and fundic regions.

It is known that *H. pylori* infection is characterized by a transient increase in acid secretion and hypochlorhydria, being a precursor for the development of active chronic gastritis, with a dense cellular infiltrate in the mucosa, which due to its persistence can cause serious damage to the gastric mucosa, which can progress to atrophic gastritis, glandular atrophy and intestinal metaplasia. The infection by the micro-organism is characterized by chronicity, which predisposes its participation in the pathogenesis of chronic gastritis, peptic ulcers (gastric and duodenal), adenocarcinoma, gastric lymphoma and recurrent abdominal pain.
